Abstract. In [V.A. Izzo *et al* 2022 *Nucl. Fusion* **62** 096029], state-of-the-art modeling of thermal and current quench (CQ) MHD coupled with a self-consistent evolution of runaway electron (RE) generation and transport showed that a non-axisymmetric ($n = 1$) in-vessel coil could passively prevent RE beam formation during disruptions in SPARC, a compact high-field tokamak projected to achieve a fusion gain $Q > 2$ in DT plasmas. However, such suppression requires finite transport of REs within magnetic islands and re-healed flux surfaces; conservatively assuming *zero* transport in these regions leads to an upper bound of RE current ~ 1 MA compared to ~ 8.7 MA of pre-disruption plasma current. Further investigation finds that core-localized electrons, within $r/a < 0.3$ and with kinetic energies ~ 0.2 – 15 MeV, contribute most to the RE plateau formation. Yet only a relatively small amount of transport, i.e. a diffusion coefficient ~ 18 m²/s, is needed in the core to fully mitigate these REs. Properly accounting for (i) the CQ electric field’s effect on RE transport in islands and (ii) the contribution of significant RE currents to disruption MHD may help achieve this.

Keywords: Runaway electrons, passive mitigation, transport, disruptions, SPARC

1. Introduction

In [1, 2], a novel method was proposed for *passive* mitigation of relativistic “runaway electrons” (REs) generated during tokamak plasma disruptions: First, an in-vessel, non-axisymmetric coil would be passively energized through mutual coupling to the plasma current during the disruption’s current quench (CQ); then, the resulting magnetic field

‡ Author to whom correspondence should be addressed: rating@mit.edu

perturbation would enhance stochasticity and transport such that the RE loss rate would dominate the growth rate, thus preventing RE beam formation.

In [3], such a “Runaway Electron Mitigation Coil” (REMC) was proposed for the SPARC tokamak [4], a high-field ($B_0 = 12.2$ T), compact ($R_0 = 1.85$ m, $a = 0.57$ m) device currently under construction in Devens, Massachusetts, USA. The present REMC design has a predominantly $n = 1$ structure and is located on the outboard wall; a similar coil is planned for the DIII-D tokamak, but on the inboard wall [5]. Several aspects of the SPARC “Primary Reference Discharge” (PRD) make the RE problem challenging: a large plasma current ($I_p = 8.7$ MA) can lead to dangerous exponential RE growth; high core temperatures $T_{e0} \approx 20$ keV can cause enhanced primary and hot-tail generation; DT fuel provides a seed of non-thermal electrons through tritium beta decay; and high energy gammas from activated materials could accelerate electrons via Compton scattering.

However, in [6], modeling of the PRD’s worst-case-scenario CQ (~ 3 ms) showed complete prevention of RE beam formation with the REMC – and ~ 5 – 6 MA of RE current without it. The modeling workflow included four steps: First, the mutual couplings of all toroidally conducting structures were simulated in COMSOL [7] to evaluate the REMC’s vacuum electromagnetic fields during the worst-case CQ. Second, these magnetic fields were applied at the boundary of a nonlinear, 3D NIMROD [8] simulation to assess the plasma response and total fields. Third, the stochastic magnetic fields were input into the orbit-following code ASCOT5 to calculate the advective and diffusive transport [9] of energetic electrons. Finally, these transport coefficients – A, D as functions of energy, pitch, and radius – were supplied to the hybrid fluid-kinetic code DREAM [10] for self-consistent evolution of the RE population. Importantly, in both NIMROD and DREAM, the REMC vacuum fields and transport coefficients, respectively, were evolved as functions of I_p and not time explicitly.

More recently, in [11], both the thermal quench (TQ) and CQ were modeled for the SPARC PRD and REMC; the results of this study – which bound the maximum expected RE current – are summarized in Section 2. Section 3 further explores these bounds in RE phase space, as well as the minimum transport needed to fully prevent RE beam formation. Finally, results and opportunities for future modeling are discussed in Section 4.

2. REMC efficacy during the thermal and current quenches

The same workflow presented in [6] and summarized in Section 1 was used in [11] to assess the SPARC REMC’s efficacy for a full PRD mitigated disruption, i.e. including both the TQ and CQ. Here, the TQ (~ 1 ms in duration) was induced by neon radiation, as in a scenario where massive gas injection was employed. The main results are captured in Figs. 1 and 2. The pre-disruption safety factor (q) profile is shown at $t = 0$ in Fig. 1a with $q(0) \sim 1$ and $q = 2$ around a normalized poloidal flux value of $\psi_N \approx 0.75$. During the TQ, i.e. the first ~ 1 ms of the simulation, the plasma current I_p decreases slightly, with the I_p -spike denoting the start of the CQ. Around that time, the magnetic perturbation amplitudes $\delta B/B$ first peak (see Fig. 1b), and strong nonlinear coupling among odd and even toroidal harmonics

is observed. Poincaré plots of magnetic field lines, in Fig. 1a, also show high stochasticity during this period.

Figure 1: (a, upper) Poincaré plots of (mostly) stochastic magnetic field lines from NIMROD within the simulation boundary (dashed) and SPARC first wall (solid). (a, lower) The safety factor q -profile evolution vs normalized poloidal flux (ψ_N) and time, with the plasma current (I_p) time-evolution overlaid. (b) Amplitudes of $n = 1-10$ modes in units of $\delta B/B = \sqrt{W_{\text{mag}}(n)}/W_{\text{mag}}(n=0)}$ with W_{mag} the magnetic energy Fourier component. Subplot (a) is reproduced from Figure 5 in [11].

However, from $t \approx 1-1.5$ ms, $q(0)$ increases from 1 to 2, and beyond $t > 1.5$ ms, the REMC is no longer resonant with the plasma core (refer to Figure 1 in [6] for more details). Although the predominantly odd externally applied fields continue to grow as the coil current continues to increase, these are now largely non-resonant fields that do not perturb the flux surfaces, and the nonlinearly excited resonant field components, both odd and even, decay away. Thus, small islands start to reform, re-healing as closed flux surfaces by $t \approx 1.8$ ms. Note that the contribution from REs to the MHD are *not* included in these NIMROD simulations, but the back-reaction is expected to be small for low RE currents early on. This will be discussed further in Section 4.

Figure 2 shows the self-consistent evolution of Ohmic and RE currents from DREAM, including the advective and diffusive transport calculated by ASCOT5 in DREAM's fluid transport model [12]. Note that the time bases of the DREAM and NIMROD simulations are not exactly the same; instead, the DREAM simulation is initialized with profiles close to the time of NIMROD's I_p -spike. Importantly, the TQ in DREAM is only modeled for the final ~ 0.1 ms of NIMROD's ~ 1 ms TQ because DREAM requires a monotonic variation

of the plasma current from which to map transport coefficients. These transport coefficients evolve with the plasma current until the final I_p -value of the NIMROD simulation; then, they are held constant in time (see the vertical dashed line in the upper part of Fig. 2).§

Figure 2: Time-traces of Ohmic (solid), RE (dot-dashed), and total (dashed) currents from DREAM; thick/thin RE currents indicate no/transport within re-healed flux surfaces. Times denoted above correspond to the NIMROD simulation (see Fig. 1). Transport coefficients are fixed in time after the vertical dashed line (upper), and surface re-healing begins at the vertical dotted line (lower). Reproduced from Figure 6 in [11].

Two scenarios for the RE current are depicted in Fig. 2: In the first, the transport coefficients are applied as calculated throughout the entire plasma domain, i.e. even inside the re-healed flux surfaces, and the RE current remains negligibly low ($\sim 1 \mu\text{A}$). However, in the second case, transport inside islands and re-healed flux surfaces is set to zero, which is perhaps overly conservative. (Explicitly, $A = D = 0$ wherever $D < 1000 \text{ m}^2/\text{s}$.) The result is a RE plateau with current $\sim 1 \text{ MA}$. While this value is an improvement upon the $\sim 5\text{--}6 \text{ MA}$ of RE current expected with *no* REMC [3, 6], it is likely the pessimistic upper bound on the true value.

Here, it is important to note that the initial hot-tail seed can be sensitive to the TQ cooling time prescribed in DREAM. In the CQ-only modeling effort of [6], a $\sim 0.5 \text{ ms}$ TQ from 20 keV to 4 eV led to a $\sim 50 \text{ kA}$ seed which was then dissipated by the REMC, with similar $\delta B/B \sim 10^{-2}$ as that in Fig. 1b. Further reducing the TQ time to 0.1 ms resulted in a much higher transient RE beam current of $\sim 1 \text{ MA}$, which was still suppressed by the REMC. These results are consistent with all test-particle REs losing confinement during the TQ in NIMROD for the scenario modeled in this paper [11]. The inclusion of TQ transport in DREAM, as a function of non-monotonic I_p variation, is left for future work.

§ To enforce transport ambipolarity in DREAM, any change of the electron density on a given flux surface due to transport is compensated by a change in the bulk electron density of similar size but opposite sign.

3. Investigating transport inside re-healed flux surfaces

This section explores further the ten-order-of-magnitude difference in the predicted RE current when transport is/not accounted for within NIMROD’s islands and re-healed flux surfaces. Radial profiles of the diffusion coefficient (D) are shown in Fig. 3a, also as a function of normalized electron momentum, at the last NIMROD simulation time; the values shown are taken at a representative electron pitch $p_{\parallel}/p = 0.8$. There are a few important notes here: (i) the diffusion coefficients span five orders of magnitude from the plasma core to edge; (ii) though not shown, the advection coefficients are of similar magnitude ($A[\text{m/s}] \sim D[\text{m}^2/\text{s}]$); and (iii) both transport coefficients are relatively insensitive to the electron pitch in the relevant range $p_{\parallel}/p \in [0.8, 1]$ (see Figure 3 in [6]).

Figure 3: (a) Diffusion coefficients, $\log_{10}(D [\text{m}^2/\text{s}])$, from ASCOT5 vs normalized minor radius (r/a) and electron momentum normalized to the rest mass ($p/m_e c$) at the time indicated by the vertical dashed lines in Fig. 2(upper) and subplot (b). (b) Time-traces of the RE current from DREAM when diffusion coefficients *less* than the noted value are set to zero, i.e. $D = 0$ *within* the similarly styled contours in (a). Note the various linear/logarithmic scales. The legend for curves in subplot (b) applies to contours in subplot (a).

In Fig. 3a, general trends are seen of rapidly decreasing transport with decreasing radius and relative insensitivity to electron energy. However, there is a clear feature of “very low” transport ($D < 30 \text{m}^2/\text{s}$) for electrons localized in the core ($r/a \sim 0.05\text{--}0.2$) and with energies $< 50 \text{MeV}$ ($p/m_e c < 100$). Figure 3b shows the time-evolution of RE current when the transport coefficients are zeroed in different regions of the phase space in Fig. 3a. The “base case” is $D = 0$ wherever $D < 1000 \text{m}^2/\text{s}$, which effectively includes the entire core, $r/a < 0.3$, and leads to the previously seen $\sim 1 \text{MA}$ RE beam. Yet reducing this threshold to $D < 10 \text{m}^2/\text{s}$ leads to negligible RE current. Thus, it is primarily the electron

|| Note that the diffusivity is used for discrimination of the phase space regions, while the advection coefficients (not shown here) are also filtered in the same regions.

population within $D \sim 10\text{--}18\text{ m}^2/\text{s}$, i.e. localized in $r/a \sim 0.05\text{--}0.2$ and with kinetic energies $\sim 0.2\text{--}15\text{ MeV}$ ($p/m_e c \sim 1\text{--}30$), which contributes most to RE plateau formation.

This problem can be looked at from another angle: What is the minimum transport needed to fully suppress RE plateau formation? More specifically, within the region of phase space where $D < 1000\text{ m}^2/\text{s}$ in Fig. 3a (that mostly coincides with the re-healed flux surface region), which constant value of D is sufficient to yield negligible RE current? As seen in Fig. 4, full RE beam prevention is only achieved somewhere in the range $D = 10\text{--}18\text{ m}^2/\text{s}$. Therefore, compared to the highly diffusive edge region ($D \approx 10^3\text{--}10^5\text{ m}^2/\text{s}$), a relatively small amount of core transport is needed. Importantly, note that the advection coefficient $A[\text{m/s}]$ is set to the same value as $D[\text{m}^2/\text{s}]$ in these phase space regions, but almost identical results are found when setting $A = 0$, as diffusion dominates in the narrow radial region of re-healed flux surfaces (as long as $A[\text{m/s}] \sim D[\text{m}^2/\text{s}]$).

Figure 4: Time-traces of the RE current from DREAM when the diffusion coefficient is set to the listed value in regions of phase space with $D < 1000\text{ m}^2/\text{s}$ in Fig. 3a. The time indicated by the vertical dashed line is the same as in Figs. 2 and 3b.

4. Discussion and summary

From the previous sections, it is clear that zeroing the transport in the core ($r/a < 0.3$) in DREAM is too conservative and pessimistic, resulting in a ~ 1 MA RE beam. Even so, it is important to note that this current is 5-6 times less than that expected for an unmitigated RE beam, i.e. no REMC, so even this conservative base case could be considered successful. ASCOT5 simulations evaluate diffusion coefficients spanning $D \approx 1\text{--}1000\text{ m}^2/\text{s}$ in the core, but encouragingly only $D \sim 18\text{ m}^2/\text{s}$ is needed in that region to completely suppress a RE beam. Perhaps this is one reason why many tokamaks struggle to generate RE plateaus via “natural” disruptions (as in Alcator C-Mod [13, 14], for example), and instead resort to special “recipes,” although lower plasma current and thus lower avalanching certainly also play a role.

However, it is not yet known whether this level of transport is achievable in SPARC. In [11], it was noted that the degree of field line stochastization predicted by NIMROD could be affected by several approximations, most notably the presence of a close, ideal wall which tends to *limit* MHD mode growth. This approximation will be explored further in future resistive-wall studies, and perhaps this minimum D -value will even decrease.

We can also approach this from another direction: In what ways can the REMC design be modified to achieve $D > 18 \text{ m}^2/\text{s}$ throughout the plasma? Perhaps most straightforward, the coil could be moved closer to the plasma and farther from the VV. This would (i) improve the plasma-coil mutual coupling and reduce the coil’s self-inductance, thereby increasing the induced coil current, (ii) decrease image currents in the conducting wall, and (iii) enhance the magnetic perturbation amplitude $\delta B/B$ in the core. Perhaps a design metric could be the expected diffusion coefficient computed from vacuum fields à la [15], $D \propto (\delta B/B)^2$. The coil resistance could also be lowered by changing the coil cross-section, length, and material (resistivity). That said, many other factors constrain the design, like available space, forces and stresses, heating, and more.

As discussed in [6], both advection and diffusion tend to increase with RE energy, but there is a roll-over when the energetic electron drift orbits effectively average over large regions of stochasticity (see Figure 3 in [6] or [16,17] and others for further details). However, for REs within healed flux surfaces, perhaps large orbits could lead to “excursions” into stochastic fields, thus enhancing transport. For example, KORC simulations in [16] found that REs with Larmor radii similar to island widths could escape them. In addition, the same electric field accelerating REs causes them to drift radially [18], and this was not accounted for in these ASCOT5 simulations, but will be pursued in the future. ¶

Perhaps most importantly, the effect of the RE population itself on the magnetic field and MHD has not yet been fully assessed. Figure 5 shows the time-evolution of the q -profile, its minimum value, and the internal inductance (ℓ_i) in DREAM for the base case. Although slightly later in time than in Fig. 1a, the central safety factor $q(0)$ also surpasses $q = 2$; however, unlike the NIMROD results, the increasing RE current then reduces $q(0) < 2$ at $t \approx 5 \text{ ms}$ and $q(0) < 1$ at $t \approx 5.5 \text{ ms}$. Thus, in theory, the REMC should regain resonance in the core beyond $t > 5 \text{ ms}$, thereby enhancing transport and reducing the RE current, but this was not captured in the current workflow. A destructive kink instability might also be expected, as seen in experiment [19,20], for such low $q(0)$ and high ℓ_i .

Even then it is not clear what overall effect this self-regulation would have on the RE beam which already has a current $\sim 1 \text{ MA}$ by $t \approx 5 \text{ ms}$ (for the base case with no island transport). Luckily, the Ohmic current has almost completely decayed by then, and the relatively long L/R time ($> 10 \text{ ms}$) of the REMC will maintain the coil current and its perturbative effect. Furthermore, any additional transport within the re-healed flux surfaces will help lower this quasi-stationary RE current. A fluid RE model that could capture this

¶ See [17] for simulations of passing and trapped REs during an ITER CQ, including the effects of collisions and the electric field.

Figure 5: DREAM results for the base case in Fig. 3b with $D = 0$ below $D < 1000 \text{ m}^2/\text{s}$: (a) evolution of the safety factor q -profile vs minor radius for five times, and (b) time evolution of the minimum q -value (dot-dashed) and internal inductance ℓ_i (solid).

effect has been incorporated into the JOREK [21, 22] and M3D-C1 [23] MHD codes; a similar model is being implemented in NIMROD [24] and benchmarked against the existing codes. Its application to the SPARC REMC will be pursued in future work.
